ABSTRACT

Transdermal delivery is an attractive alternative to conventional techniques for administration of systemic therapeutics. The major challenge in designing transdermal drug delivery systems is to overcome the natural transport barrier of the skin. One approach is the use of vesicle formulations. Liposomes were first shown to be of potential value for topical therapy by Mezei and Gulasekharam in 1980, since then investigation continued towards development of lipid vesicles as carriers for skin delivery of drugs. But still vesicles are considered as a controversial class of dermal and transdermal carriers. This review provides an overview of the effectiveness of conventional, deformable and ethosomal vesicles as drug delivery systems as well as their possible mode of action as permeation enhancers or transdermal drug carriers. Deformable liposomes and ethosomes penetrate stratum corneum, thus releasing their drugs or proteins into systemic circulation. Vesicles as carrier systems can give rise to development of novel transdermal drug delivery systems.

Keywords: Transdermal, Dermal, Liposomes, Transferosomes, Ethosomes, Invasomes.

INTRODUCTION

Transdermal drug delivery is a viable administration route for potent, low molecular weight therapeutic agents which cannot withstand the hostile environment of the gastro-intestinal tract and /or are subject to considerable first pass metabolism by the liver. It uses the skin as an alternative route for the delivery of systemically acting drugs. Dermal drug delivery is the topical application of drugs to the skin in the treatment of skin diseases, wherein high concentrations of drugs can be localised at the site of action, thereby reducing the systemic drug levels and side effects. 1-3

The skin covers a total surface area of approximately 1.8m² and provides the contact between the human body and its external environment. The stratum corneum, the outermost layer of the skin acts as the main barrier in the skin. The structure of the stratum corneum is often compared to a brick wall, with the keratin-rich corneocytes as the bricks surrounded by the mortar of the intercellular lipid lamellae. Two main routes of skin permeation are the transappendageal route and transepidermal route. The transappendageal route also known as the shunt route includes permeation through the sweat glands and across the hair follicles with their associated sebaceous glands. The transepidermal route contains two micropathways, the intercellular route and transcellular route as shown in fig 1. The intercellular route is a continuous way through intercellular lipid domains and tranacellular pathway through the keratinocytes, then across the intercellular lipids. Naturally all molecules traverse by a combination of all three routes, the relative importance of which route depends on the molecules physico-chemical characteristics. 4-5

It has been generally accepted that the highly organised crystalline lipid lamellae play an essential role in the barrier properties of the stratum corneum. Many techniques have been aimed to disrupt and weaken the highly organised intercellular lipids in an attempt to enhance drug transport across the intact skin or to increase the delivery force for the permeation of drugs across this skin barrier. 6-8

One of the most convenient methods is the use of vesicle formulations as skin delivery systems.

The rationale for using vesicles in dermal and transdermal drug delivery is many folds. 5-8/Vesicles might:

a) Act as drug carriers to deliver entrapped drug molecules into or across the skin.

b) Act as penetration enhancers for the penetration of the individual lipid components into the stratum corneum and subsequently altering the intercellular lipid lamellae within this skin layer.

c) Serve as a depot for sustained release of dermally active compounds

d) Serve as a rate limiting membrane barrier for the modulation of systemic absorption, hence providing a controlled transdermal delivery system.

Conventional liposomes as skin delivery systems

Liposomes are lipid vesicles that fully enclose an aqueous volume. Lipid molecules are usually phospholipids with or without some additives. Cholesterol may be included to improve bilayer characteristics of liposomes, increasing the microviscosity of the bilayers which in turn reduces the permeability of the membrane to water soluble molecules. This also results in the stabilization of the membrane and increase in the rigidity of the vesicles. Many methods for preparations of liposomes are described in literature. Most commonly used is the film hydration method. 9

The potential value of liposomes for topical therapy was first introduced by Mezei and Gulasekharam (1980). 10 In this study, greater four to five fold triamcinolone acetonide concentrations in the epidermis and dermis with lower systemic drug levels were observed when the drug was delivered from liposomal lotion in comparison with conventional formulations of the same drug concentrations. 10

Several in vivo and in vitro transport studies reported that conventional liposomes only enhanced skin deposition, mostly by reducing ( or no effect ) the percutaneous permeation or systemic absorption of hydrocortisone, 11,12,13 corticosteroids, 14 lidocaine, 15 tretinoin, 16 and ciclosporin. 17

Fig. 1: A schematic representation of the skin showing the transcellular and intercellular routes of penetration.
These results suggested that conventional liposomes were useful for topical/dermal delivery of these drugs. Lipid composition, method of preparation and thermodynamic state of the bilayers of liposomes were all shown to greatly affect skin deposition behaviour of liposomes.\textsuperscript{18} Dermal delivery with skin-lipid liposomes was shown to be more effective than delivery with phospholipid vesicles.\textsuperscript{19} A decrease in cholesterol content in vesicular bilayers, which increases fluidity of the bilayers, resulted in increasing the drug transport across the stratum corneum. Recently it was evident that classic liposomes are of little or no value as carriers for transdermal delivery, as they do not deeply penetrate the skin. But rather remain confined to the upper layers of the stratum corneum. Confocal microscopy studies showed that intact liposomes were not able to penetrate into granular layers of the epidermis.\textsuperscript{20}

Due to the large size of the liposomes as stated by El Maghraby,\textsuperscript{21} they were not able to enter the capillary circulation and thus acted as reservoirs for the drug at the site of action. Though liposome lipids penetrate into the stratum corneum by adhering onto the surface of the skin and subsequently destabilising, fusing or mixing with the lipid matrix, they may act as penetration enhancers by loosening the lipid structure of the stratum corneum and promoting impaired barrier function of these layers to the drug with subsequent increase in the skin partitioning of drug.\textsuperscript{22} From the above observations we can infer that dermal delivery with skin-lipid liposomes is more effective than delivery with phospholipid vesicles.\textsuperscript{23}

**Mechanism of action of liposomes**

In the free drug mechanism (Fig. 2 at A) the drug permeates through skin after exiting from the vesicles\textsuperscript{25}. In the penetration enhancing mechanism (Fig. 2 at B) after application of vesicles, changes in the ultrastructures of the intercellular lipids were seen suggesting a penetration enhancing effect.\textsuperscript{26} In vesicle adsorption to and/or fusion with the stratum corneum (Fig. 2 at C) the vesicles may adsorb to the stratum corneum surface with subsequent transfer of drug directly from vesicles to skin or vesicles may fuse and mix with the stratum corneum lipid matrix, increasing drug partitioning into the skin.

Fig.2: Possible mechanisms of action of liposomes as skin drug delivery systems. (A) is the free drug mechanism, (B) is the penetration enhancing process of liposome components, (C) indicates vesicle adsorption to and/or fusion with the stratum corneum (SC) and (D) illustrates intact vesicle penetration into and through the intact skin and (E) the transappendageal route.\textsuperscript{24}

The interaction of liposomes with human skin has been reviewed and it was concluded that they can be taken into the skin but cannot penetrate through intact healthy stratum corneum, instead they dissolve and form a unit membrane structure.\textsuperscript{27} In intact vesicular skin penetration mechanism, (Fig.2 at D) traditional liposomes with intact vesicles cannot penetrate the human skin but ultraformable liposomes have been reported to invade the skin intact and go deep enough to be absorbed by the systemic circulation.\textsuperscript{28}

The transappendageal penetration (Fig. 2 at E) route plays a minor role in transdermal delivery from liposomes. Electron microscopy indicated that liposomes 600nm in diameter can penetrate through skin but those of 1000nm or more remain interiorised in the stratum corneum. Deposition was higher in hairy guinea pigs but with regard to penetration through skin, no difference could be found between hairless and hairy guinea pigs. Also, vesicular delivery through shunts was excluded on the basis that there were no significant variations between different animals or humans with diverse densities of hair follicles, with regard to the transferosomal input of insulin.\textsuperscript{29} The transfollicular delivery from liposomes was enhanced only after it was combined with iontophoresis technique.\textsuperscript{30}

**Niosomes as skin delivery systems**

Niosomes are composed of non-ionic amphiphiles (surfactants) and are similar in function to liposomes.

Niosomes constructed from a new non-ionic surfactant alpha, omega-hexadecyl-bis-[1-aza-18-crown-6] (bola-surfactant), span 80 and cholesterol show significantly improved percutaneous permeation of ammonium glycyrrhizinate\textsuperscript{30} with respect to both the aqueous drug solution and a physical mixture between unloaded bola-niosomes and the aqueous drug solution. Niosomes constructed from cholesterol, span 60 and diocyl phosphate were effective in increasing skin permeation of fumaglide across mouse skin as compared to conventional formulations.\textsuperscript{31}

**Defoamable Liposomes as skin delivery systems**

Over the past 15 years, intensive research led to the introduction and development, of a new class of highly defoamable (elastic or ultraflexible) liposomes that have been termed transferosomes.

Transferosomes are ultraformable hydrophilic lipid vesicles that putatively cross the skin under the influence of a transdermal water activity gradient. Transferosomes consist of phospholipids and an edge activator that increases the deformability of the bilayers and is often a single chain surfactant such as sodium cholate, sodium deoxycholate, Span 60, Span 65, Span 80, Tween 20, Tween 60, Tween 80 or dipotassium glycyrrhizinate.\textsuperscript{32} The edge activator confer ultraformability on the transferosomes and allow them to squeeze through channels in the stratum corneum that are less than one-tenth the diameter of the transferosome. The driving force for penetration into the skin is the "transdermal gradient" caused by the difference in water content between the relatively dehydrated skin surface (approx 20% water) and the aqueous viable epidermis (close to 100%).\textsuperscript{33}

Vesicles can be applied occlusively or non-occlusively. The difference in skin interaction between occlusive and non-occlusive application is of importance for defoamable vesicles. As the transport of transferosomes is driven by the osmotic gradient across the skin occlusion, span 60 and diocyl phosphate would enhance this osmotic gradient and is therefore detrimental for the actions of the defoamable vesicles.\textsuperscript{34,35}
Mechanism of action of deformable liposomes

Deformable liposomes can penetrate through stratum corneum by two mechanisms. First, vesicles can act as drug carrier systems, whereby intact vesicles enter the stratum corneum carrying vesicle-bound drug molecules into the skin. Secondly vesicles can act as penetration enhancers, whereby vesicle bilayers enter the stratum corneum and subsequently modify the intercellular lipid lamellae. This will facilitate penetration of free drug molecules into and across the stratum corneum.20, 39

In the first mechanism the driving force for the vesicles entering the skin is xerophoria (the tendency to avoid dry surroundings). 35, 60 The difference in penetration between deformable liposomes and traditional liposomes is the high and stress-dependent adaptability of such deformable vesicles which enables them alone to squeeze between the cells in the stratum corneum, despite the large average vesicle size (Fig.3). Thus, they can trespass the intact skin spontaneously, under the influence of the naturally occurring in-vivo cutaneous hydration gradient intact without permanent disintegration. 35, 36, 40

**Fig.3:** Ultra-deformable transferosome squeezing through minute pores in the stratum corneum, driven by the water concentration gradient. The modified liposome thus penetrates from the horny layer surface (relatively dry) to the wet viable tissues. 4

The intact vesicular permeation into the stratum corneum and the penetration enhancing effect play a role in the enhanced skin delivery of drugs by deformable liposomes under non-occlusive conditions and it suggest’s that one of the two mechanisms might predominate the other according to the physico-chemical properties of the drug. The transport of drug by deformable liposomes into the stratum corneum bypassing the main barrier for drug permeation will considerably improve skin delivery. Ultra-deformable vesicles have been shown to be successful in delivering a range of different drugs across the skin including 5-fluouracil, 41 lidocaine, 62 tetracaine, 62 cyclosporin A, 63 insulin, 64 diclofenac, 60 triamcinolone acetonide, 43, 66 hydrocortisone, 67 dexamethasone, 67 levonorgestrel, 72 estradiol, 86 low molecular weight heparin, 39 methotrexate, 90 dipotassium glycyrrhizinate 53 and zidovudine. 53

**Ethosomes as skin delivery systems**

Ethosomes are novel lipid carriers composed of phospholipid, ethanol and water and are recently developed by Touitou et al. 51, 52 Liposomal formulations containing up to 10% ethanol and up to 15% propylene glycol were previously described by Foldvari et al. but the use of high ethanol content was first described by Touitou et al. 52 for ethosomes. Due to the interdigitation effect of ethanol on lip bilayers, it was believed that high concentrations of ethanol are detrimental to liposomal formulations.

Ethosomes are novel permeation-enhancing lipid vesicles embodying high concentration (20-45%) of ethanol and are prepared by dissolving the lipids and drug in ethanol. The aqueous component is added slowly in a fine stream at a constant rate in a well sealed container with constant mixing. Mixing is then continued for additional five minutes. 53

A characteristic feature of ethosomes is their small size relative to the liposomes. This could be due to their incorporation of high ethanol concentration, which confers a surface negative net charge to the liposome which causes the size of vesicles to decrease. The size of ethosomal vesicles were reported to increase with decreasing ethanol concentration in the range of 20-45 %. Presence of ethanol allows for better solubility of many drugs thus exhibiting high encapsulation efficiency for a wide range of molecules including lipophilic drugs. 55, 57

Ethosomes were reported to improve in vivo and in vitro skin delivery of various drugs both under occlusive and non-occlusive conditions.

**Mechanism of action of ethosomes**

The fig.4 illustrates a hypothetical model of how ethosomes may enhance penetration of drugs through stratum corneum lipids. The stratum corneum liposomes multilayers are densely packed and highly conformationally ordered at physiological temperature.

Ethanol interacts with lipid molecules in the polar head group region, resulting in a reduction in the T<sub>c</sub> of the stratum corneum lipids thus increasing their fluidity. The intercalation of ethanol into the polar head group can result in an increase in the membrane permeability. Ethanol may also provide the vesicles with soft flexible characteristics which allow them to more easily penetrate into deeper layers of the skin. The ethosome vesicles can penetrate through the disordered stratum corneum. The release of drug in the deeper layers of the skin and its transdermal absorption could be the result of fusion of ethosomes with skin lipids and drug release at various points along the penetration pathway. 58 The effect of ethanol on stratum corneum lipids and on vesicle fluidity as well as dynamic interaction between ethosomes and the stratum corneum may contribute to the superior delivery properties. Ethosomes have been used both in vivo and in vitro for the delivery of various drugs across skin such as minoxidil, 53 testosterone, 53 acyclovir, 59 cannabidiol, 60 erythromycin, 64 ammonium glycyrrhizinate, 62 sotalol, 62 sodium salicylate, 62 propanol, 63 trihexyphenidyl, 64 zidovudine 65 and azelalacid. 66

**Invasomes as carriers for skin delivery systems and their mechanism:**

Several lipophilic and hydrophilic penetration enhancers (i.e. labrasol, transcutol and cineole) were tested and penetration enhancer – containing vesicles have been introduced where there is enhancement in penetration due to the penetration enhancers. 57 Such penetration enhancer containing vesicles with terpenes as penetration enhancers were termed as invasomes.

Invasomes composed of phosphatidylcholine, ethanol and a mixture of terpenes as penetration enhancers have been introduced by Verma and Fahr’s group. 66 In addition to the mechanism of penetration enhancement of elastic vesicles terpenes which are considered as potent penetration enhancers increase drug permeation by disrupting lipid packaging of stratum corneum and/or disturbing the stacking of the bilayers. 69

Penetration enhancer-containing vesicles have been used as carriers for Minoxidil 60, Diclofenac 60 and Temoporfin 60. Vesicles being studied as carriers for skin delivery and their proposed mechanism have been listed in table1 taking some examples into consideration.

17 ethosomes Ketotifen PC (4.25%) & Ethanol (30%)

and stratum corneum lipids, thus providing a greater malleability to the vesicles and enhancing permeability of the skin.

Ketotifen should be incorporated in ethosomal vesicles for optimum skin delivery as ethosomes were not able to improve skin delivery of non-entrapped ketotifen.

18 ethosomes 5-aminolevulinic acid PE & Ethanol

Ethanol interacts with the skin and extracts lipids of the stratum corneum, and fluidized stratum corneum lipids create channels which allow the increased delivery of a drug

The penetration ability of ethosomes was greater than that of liposomes.

19 Penetration enhancer-containing vesicles minoxidil Soy lecithin, Dicetylphosphate, Labrasol, Transcutol, Cineole

Intact vesicle penetration by entering the stratum corneum where they form a depot from which the drug is slowly released.

Penetration enhancer-containing vesicles can be a potential innovative carriers for improving topical delivery of minoxidil.

20 Invasomes Temoporfin PC; Ethanol (75:25) & Terpenes (0-1%)

Synergistic effect of liposomes, terpenes and ethanol

Invasomes containing 1% of terpene mixture present an effective drug carrier system for delivering the highly hydrophobic drug Temoporfin into the stratum corneum and deeper layers of skin.

**CONCLUSION**

In summary, from the aforementioned studies, it is evident that liposomes offer potential value in dermal and transdermal drug delivery and recent advances and modifications appear to have generated increased therapeutic potential. Alteration in their composition and structure results in vesicles with tailored properties. Flexible and ultra-deformable liposomes are such advances with claims of enhanced transdermal drug delivery to efficiencies comparable with sub-cutaneous administration.

However, a detailed knowledge of the mode of action is necessary in order to assess the full potential of elastic vesicles as skin delivery vehicles, such as the delivery of large molecules or targeting certain sites and cells within the skin. This is only possible when vesicles act as carrier systems and could give rise to the development of very interesting and novel transdermal drug delivery systems. Table 1 (vesicles being studied as carriers for skin delivery and their proposed mechanism) shows that deformable liposomes and ethosomes are better carriers for transdermal delivery when compared with liposomes and niosomes.

So, a vesicle formulation that rapidly enters the stratum corneum and remains in the deepest layers of stratum corneum releasing their drugs or proteins has useful advantages and is an important area of study to investigate such a promising approach.
